The NASA STI Program Office ... in Profile

Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the lead center for NASA's scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA's institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers, but having less stringent limitations on manuscript length and extent of graphic presentations.
- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.
- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

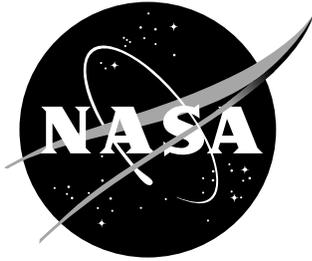

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or co-sponsored by NASA.
- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.
- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services that complement the STI Program Office's diverse offerings include creating custom thesauri, building customized databases, organizing and publishing research results ... even providing videos.

For more information about the NASA STI Program Office, see the following:

Abstract

AS&M, Inc. performed finite element analysis, with and without discrete damage, of a composite semi-span test article that represents the Boeing 220-passenger transport aircraft composite semi-span test article. A NASTRAN bulk data file and drawings of the test mount fixtures and semi-span components were utilized to generate the baseline finite element model. In this model, the stringer blades are represented by shell elements, and the stringer flanges are combined with the skin. Numerous modeling modifications and discrete source damage scenarios were applied to the test article model throughout the course of the study. This report details the analysis method and results obtained from the composite semi-span study. Analyses were carried out for three load cases: Braked Roll, 1.0G Down-Bending and 2.5G Up-Bending. These analyses included linear and nonlinear static response, as well as linear and nonlinear buckling response. Results are presented in the form of stress and strain plots, factors of safety for failed elements, buckling loads and modes, deflection prediction tables and plots, and strain gage prediction tables and plots. The collected results are presented within this report for comparison to test results.

1. Introduction

AS&M, Inc. was contracted by NASA Langley Research Center to perform a number of analyses on the Boeing 220-passenger transport aircraft composite semi-span test article. The government provided a NASTRAN finite element model and the drawings necessary for creation of a STAGS finite element model. Loading and damage conditions were also specified, and detailed analyses were conducted when required. This report details the methods and results from work completed by AS&M on the composite semi-span test article.

A NASTRAN finite element model of the Boeing composite semi-span test article, dated January 24, 1996, was provided to AS&M. In this finite element model, stringers, rib stiffeners and intercostals were modeled as offset beams, while the skin was modeled with plate elements. The NASTRAN bulk data file was imported into a PATRAN database for modification, and several STAGS models were developed from the new database for use in the various analyses conducted. Material properties used in the newly developed models were also obtained from the NASTRAN bulk data file and from additional provided documentation. Finite element models were developed both with and without discrete damage. Details of the finite element models, modeling techniques and discrete source damage are discussed in Sections 3 and 4 of this report.

The STAGS finite element analysis program was used to analyze the newly developed models under three load conditions. These load cases, namely Braked Roll, 1.0G Down-Bending and 2.5G Up-Bending are described in Section 2 of this report titled Load Case Definitions. Linear and nonlinear analyses were carried out for these three load cases to determine the static and buckling response of the composite semi-span. Results are presented in the form of stress and strain plots, factors of safety for failed elements, buckling loads and modes, deflection prediction tables and plots, and strain gage prediction tables and plots.

2. Load Case Definitions

2.1 Description

AS&M investigated the composite semi-span response under three load cases. Experimental loads are applied to the test article by means of load cell actuators which are numbered and located as shown in Figure 2.1. Actuator Design Ultimate Loads (DUL) values for the three cases are given in Table 2.1. The three load cases are as follows: load case 1 is 1.0G Down-Bending, load case 2 is 2.5G Up-Bending and load case 3 is Braked Roll. Loads are introduced into the finite element model as point loads at the appropriate nodes. Figures 2.2-2.4 show the three load cases as applied to the loads model (defined in Section 3.3.1). Although during the experiment the direction of the applied load can vary depending upon the deflection of the test article, and therefore affect the orientation of the load, load directions are fixed during the initial analyses since the change of orientation is expected to be minimal. All applied loads in the initial analyses act parallel to the global z-axis, with the exception of the actuator 7a load in Braked Roll. This actuator 7a load is decomposed to 110100 lbs. in the global y-direction and 150750 lbs. in the global z-direction. Follower loads at actuator 7a were later deemed necessary as described in Section 11. For all nonlinear runs except those discussed in Section 11, the load factors given in Table 2.2 are used at the corresponding load steps. Table 2.3 shows the load factors and load steps used during the follower load analysis of Section 11.

3. Models and Modeling Technique

3.1 Method

Model data was provided to AS&M, Inc. in the form of a NASTRAN bulk data file, a limited number of drawings and other documentation. Models were generated for the current study by importing the NASTRAN bulk data file into a PATRAN database, then making the required modifications. These models were then analyzed with the STAGS finite element analysis software using 210 beam elements, 310 triangular shell elements and 410 quadrilateral shell elements. Beam section properties were taken directly from the NASTRAN bulk data file when possible, or calculated from geometric specifications. Composite material equivalent properties are provided for "stacks" of 10 plies, and components are defined by specifying the number of stacks. Differences in shell element thicknesses were accounted for by using appropriate offsets where necessary. Upper and lower cover skin elements having a thickness of 5 stacks serve as a baseline and are specified to have no element offset. All other skin (and subsequent skin/flange) elements are given an offset that guarantees that the outer surface is continuous and smooth. Similarly, the test mount fixtures are modeled with offsets such that the interior surface is continuous and smooth, with the thickness of 1.3 inches and more having zero offset.

3.2 Model Development/Evolution

Six new finite element models were developed in this study and have been termed the loads model, refined model, detailed model, strain gage model, tapered-height model and loadarm model. The loads model was developed first in order to study the response of the root mount fixture. The refined model was then developed to study the response of the composite semi-span itself. Buckling response problems discovered using the refined model, as discussed in Section 7.2.1, required a modifications which lead to the detailed model. Next, strain gage predictions were made using the strain gage model, which has refinements to the detailed model at the strain gage locations. A tapered-height model was then developed to account for design changes that occurred in the stringer geometry of the upper cover stringer runouts. Lastly, a loadarm model was developed to study the effect of the braked-roll loading on the loadarm deflections under follower loads. Variations of these models, with the exception of the loads and loadarm models, were also studied with discrete damage introduced as required.

3.3 Model Descriptions

The composite semi-span test article consists of upper and lower covers, fore and aft spars, ribs, stringers, stiffeners and intercostals that connect the ribs to the covers and spars. Figures 3.1 and 3.2 show the upper and lower cover planforms, respectively, with the rib and stringer numbering schemes indicated. Table 3.1 summarizes the stringer termination locations that can be seen in the figures. The ribs and fore and aft spars connect the upper and lower covers. Attachment of the semi-span to the wall is accomplished with a set of test mount fixtures. Appropriate models for the semi-span and test mount fixtures are developed focussing on the area(s) of interest. Descriptions of the basic models are provided in the following sections.

3.3.1 Loads Model

As previously mentioned, the loads model was developed to analyze the root mount fixture. The geometry for the root mount fixture was generated from information provided in the form of drawings and from the NASTRAN finite element model. The root mount fixture consists of four (4) upper and four (4) lower mount plates, as well as side shear plates. A single drawing of one each for the upper and

lower mounting plates was provided. The reference surfaces were generated based upon the thickness of the plates and the required offset, with thicknesses of 1.3 inches and more represented by their mid-planes with zero offset. These surfaces were discretized and the resulting shell finite element mesh is shown in Figure 3.3, with free edges shown in Figure 3.4. Meshing of the mount plates is highly depended upon the location of the bolts that attach the mount plates to the semi-span. Bolts can not be located over stringers, and therefore were spaced between the stringer locations. Four rows of bolts attach the upper and lower plates to the semi-span covers, and three rows attach the shear plates to the semi-span spars. Figure 3.5 shows the locations of the attachment bolts, which were modeled as beam elements with high stiffness.

Side shear plates attach the upper and lower fore and aft mount plates. These shear plates are attached to the upper and lower mount plates between the wall and wing root, but are not attached the upper and lower mount plates outboard of the root rib. Separation of the shear plates and upper and lower mount plates is due to cutouts that are present to permit the semi-span overhangs (not present in the loads model) to extend fore and aft of the shear plates. Bolts then attach the free portion of the shear plates to the semi-span spars. The upper and lower plates are numbered from the leading edge to the trailing edge, with plate 1 located at the leading edge and plate 4 located at the trailing edge for both upper and lower, as seen in Figure 3.6. At these plate separations, the shear flow at the wall must be zero. To ensure this condition, the nodes located at the junctions of the plate separations and the wall have been left free, that is, no boundary conditions are imposed at those nodes during the finite element analysis. This is also done to eliminate the stress singularities that occur at corners having one clamped and one free edge. Additionally, the root mount plates have been designed such that no moments are to be generated at the wall. Therefore, all other root mount plate nodes located at the wall have only their translational degrees of freedom restrained. The completed loads model consisted of 9346 nodes and is shown in Figure 3.7.

3.3.2 Refined Model

A refined model was produced to study the response of the composite semi-span test article. In the refined model, the stringer and spar-cap beam approximations used in the NASTRAN model were replaced with appropriate shell elements. Corrections to the rib thicknesses were also made in accordance with the values shown in Table 3.2. Door covers that were absent on the provided NASTRAN model were added to the ribs. Lastly, various stiffener and cutout sizes and locations on the ribs were corrected where the NASTRAN model did not match with the current semi-span design. Rib stiffener and intercostal offset beam approximations were retained from the loads model.

Stringer flanges were incorporated with the cover skins through the introduction of skin/flange elements. Additional shell properties, with offsets, were created for the combined skin/flange. The stringer blades were introduced with additional shell elements, with new shell properties created for the stringer blades having zero offsets. NASA provided the stringer flange and blade definitions, and although the stringers were created by folding out the flanges from the blade stacks, the provided flange thicknesses are slightly smaller than what is expected from direct stack calculations. These smaller flange thicknesses were added to the skin thickness to create the skin/flange property sets. Blade thicknesses are equal to the expected thicknesses given by the number of stacks.

Rib property sets were modified to reflect the new thicknesses provided. The rib 2 doors were included in the refined model using equivalent shell properties that were determined from the door stacking sequence. Although the flexibility of the bolted door should be accounted for through

reductions in the door equivalent shell properties, such reductions were not included in this model. Equivalent beam properties for the rib 2 doors were also calculated and added to the refined model.

Detailed information provided by NASA regarding the spar/skin attachment indicates that interleaving of the spar and skin exists. Part of this attachment region includes a 4.25 inch overhang that has 6 stacks everywhere. The flange portion interior to the spars is blended with the skin so that there are 6 stacks minimum in this flange region. The flange area takes on the skin value when the skin is greater than six stacks (i.e., a 5 stack skin bay has 1 stack added to make a flange area with 6 stacks, while a 7 stack skin bay area has a flange area of 7 stacks). Essentially, this means that a flange of 6 stacks is added when the skin thickness is 5 or less stacks, and when the skin thickness is 6 or more stacks there is no separate flange. Appropriate property sets and elements were added to account for the fore and aft overhangs and spar-cap flanges.

Several areas of the basic mesh were refined to capture localized effects. Four rows of elements were created in the overhang to increase the chance of finding any overhang buckling response. The area around the stringer 1 runout on the upper cover was also refined due to a buckling problem that was found in this area (see Section 7.2.1.1). This mesh refinement included the stringer blade, stringer flange, the surrounding skin bays between ribs 4 and 5 and between ribs 5 and 6, and the forward overhang. Additional property sets were also created to define the stringer blade stack drop-off regions present for the upper cover stringer terminations. Lastly, the overhang was reduced to 1.65 inches to eliminate the myriad of overhang buckling modes found during the study of the skin bay buckling. Figure 3.8 shows the complete refined model finite element mesh that has 16937 nodes.

3.3.3 Detailed Model

The detailed model was created due to the buckling problems that were encountered during the refined model analysis. A modification was made to the refined model, where 1 stack of upper cover material was added to the upper cover skin bay bounded by rib 4, the forward spar, rib 5, and stringer #2. This modification was made by adjusting the element property set assignments, yielding the detailed model which is the base model for subsequent analysis and model development. The only additional change was to create a model with a reduced overhang length, 4.0 inches, based upon the buckling response (see Section 7.2.2.3). This modification was accomplished by adjusting the exterior row of elements of the overhangs to meet the new overhang length. The detailed model has the same number of nodes as the refined model shown in Figure 3.8, and the same mesh with the exception of the exterior rows of elements on the overhangs.

3.3.4 Strain Gage Model

The strain gage model was developed from the detailed model by modifying the regions surrounding the strain gages. These regions were refined to include only reasonably shaped quadrilateral elements in the general vicinity of the strain gages. Transition of these regions with the remainder of the model was performed using combinations of triangular elements and trapezoidal quadrilateral elements. Strain gage regions were successively refined during a convergence study, described in Section 9.1. The model yielding the converged results, consisting of 29586 nodes, is the strain gage model. Figures 3.9 and 3.10 provide views showing the upper cover and lower cover strain gage refinements, respectively.

3.3.5 Tapered-Height Model

A design change in the upper cover stringers #2 and #10 was included in the tapered-height model, where these stringer terminations are modified to now have a height taper. The initial design as modeled in the refined model includes a thickness taper which is achieved by ply drops every 3 inches while the stringer height remains constant. However, an 8 degree angle height taper is now incorporated into the stringers #2 and #10 runouts. For these 2.5 inch tall stringers, this taper angle produces a tapered region that is approximately 17.788 inches in length. Modifications were made to the base model, which was taken as the converged strain gage model of Section 3.3.4. As much as possible, the mesh remains unchanged for the modified taper geometry with the following exceptions. For stringer #2, the base model has larger elements at the actual termination since this region was of little interest in the strain gage and damage predictions. Therefore, it was necessary to slightly refine the mesh at the end of the tapered runout to accurately capture the load transfer from the stringer to the skin. Modifications to stringer #10 include additional splits in elements away from the termination, and blending of element rows into the new tapered edge via triangular elements. 30749 nodes comprise the tapered-height model. Close-ups of the upper cover stringer #2 and stringer #10 mesh refinements can be seen in Figures 3.11 and 3.12, respectively. The associated cover mesh refinements are shown in Figures 3.13 and 3.14.

3.3.6 Loadarm Model

A loadarm model was necessary to incorporate the changes in the loadarm region that is required for the braked roll loading condition. From drawings provided by NASA, and from a NASA provided NASTRAN input file called flat.bdf, the loadarm region that includes the loadarm plate, loadarm I-beam and upper and lower cover doublers was modified. The loadarm plate is the portion of the loadarm assembly that attaches the load actuator to the loadarm I-beam via two "super-bolts". Doublers are bolted to the I-beam section flanges and to the upper and lower covers, tying the I-beam flanges to the covers. The I-beam is also connected to the aft spar via angle plates that are bolted to the span and the I-beam web. Figure 3.15 shows the finite element mesh for the loadarm assembly with the individual components being labeled. Numerous changes were made to the tapered-height model to create the loadarm model.

First, since the loads outboard of rib 7 are low for the braked roll case, and the response in the outboard region was not of primary concern, the mesh outboard of rib 7 was made more coarse by eliminating all refinements associated with strain gages and discrete damage. Additionally, several of the refinements inboard of rib 7 were eliminated or modified to match the current geometry changes.

Second, the loadarm plate geometry was generated and the finite element mesh created. This includes a beam element to represent the load actuator, as well as beams to represent the actuator connection fitting that attaches the end of the actuator to the loadarm plate. The beam representing the load actuator is given an area of zero to provide no axial stiffness, while it has large moments of inertia to prevent actuator bending and torsion. Actuator connection beams were provided with large area and moments of inertia to represent the highly rigid connection fitting. In the model, the load actuator beam has a node that is coincident with the node attached to the actuator connection beams. These nodes are then translationally tied together through Lagrange constraints defined on the STAGS G3 and G4 records, which enforce compatibility of the translational degrees of freedom for the two nodes. The actuator load is then applied to the node attached to the load actuator beam so that this load becomes a follower load with respect to the load actuator and not the loadarm plate. Finally, the anchor node for the load actuator beam was fixed in all three translations, and was also fixed in rotation about the y-axis to eliminate rigid

body rotations. Figure 3.16 shows the loadarm plate, radial super-bolt connection beams, load cell connection fixture beams and load actuator beam.

Third, the planforms of the upper and lower doubler plates were corrected to represent the current design, and new doubler plate surfaces were generated. These surfaces were then subdivided according to thickness changes in the doublers and the bolt locations. This was done to ensure that meshing of the surfaces provided nodes at or near the bolt locations so that when nodes were positioned at the correct bolt locations, distortion of the finite element mesh was minimized. Similar steps were applied to the semi-span covers for generating the mesh and bolt locations. Meshes for the upper and lower doubler plates are shown in Figure 3.17.

Fourth, the I-beam was matched to the doubler plates and the aft spar. Meshing of the I-beam flanges was linked to the bolt locations of the doublers and the web location, while meshing of the web was linked to the location of the super-bolts and spar elements. The angles connecting the I-beam web to the aft spar were ignored in this model, therefore, the I-beam web elements were directly connected to the aft spar elements.

Lastly, the super-bolts were modeled as beams that were connected to the loadarm plate by stiff beams. The radial beams were located so that they were centered about the expected line of action of the forces acting on the loadarm plate, and extend through an arc of approximately 150 degrees. The radial super-bolt connection beams are clearly seen in Figure 3.16.

The finite element mesh for the entire loadarm model is shown in Figure 3.18. The loadarm model has a total of 24370 nodes.

4. Discrete Damage Definitions

4.1 Upper Cover Sawcut

The first discrete damage scenario is a 7.0 inch long by 0.19 inch wide sawcut with 0.19 inch diameter semi-circular ends. This sawcut is introduced into the upper cover skin and stringers. It is centered between ribs 10 and 11, and is centered across stringer 8, where both the cover and the stringer blade are completely cut through the thickness. Figure 4.1 shows a close-up view of the finite element mesh in the upper cover sawcut region. The same region is shown in Figure 4.2 where only the element free edges are displayed, clearly showing the crack edge and the stringer blade edges. Addition of the upper cover sawcut increases the size of the detailed model from 16937 nodes to 20016 nodes.

4.2 Lower Cover Sawcut

The second discrete damage scenario is also a 7.0 inch long by 0.19 inch wide sawcut with 0.19 inch diameter semi-circular ends. However, this sawcut is introduced into the lower cover skin and stringers. As with the upper cover sawcut, this lower cover sawcut is centered between ribs 10 and 11, and is centered across stringer 8, where both the cover and the stringer blade are completely cut through the thickness. Figure 4.3 shows a close-up view of the finite element mesh in the lower cover sawcut region. The same region is shown in Figure 4.4 where only the element free edges are displayed, clearly showing the crack edge, stringer blade edges and cutout edges. The detailed model size increases from the 16937 nodes to 20148 nodes with the addition of the lower cover sawcut.

5. Effects of Geometric Nonlinearity

5.1 Discussion

Both linear and nonlinear analyses were carried out on the detailed model and the tapered-height model to investigate the effects of geometrically nonlinear effects. Load/deflection curves for the detailed model are plotted for several nodes up to DUL, and are shown in Figures 5.1-5.8. Mild nonlinearity, i.e., small deviation from linear response, is seen for several of these nodes. Table 5.1 shows the percent deviation of the nonlinear response at DUL compared to linear extrapolation for the nodes referenced in Figures 5.1-5.8. The linear extrapolations shown in the figures and referenced in Table 5.1 are based upon the response at a load factor of 0.2, which is extrapolated to the 1.0 load factor representing DUL. The nodes discussed exhibit the most nonlinear response of all nodes observed in the model. As seen in Figure 5.9, an exaggerated deflection plot for the upper cover from rib 2 to rib 10, the overhangs exhibit mildly nonlinear deflections.

Similarly, examination of the strains in the vicinity of the upper cover stringer #10 runout also indicates mildly nonlinear response. A close-up of the strain values for this region are shown in Figures 5.10 and 5.11, showing the bottom surface spanwise strain in the tapered-height model for both the linear and nonlinear analyses, respectively. Maximum strain values for the linear analysis occur at the stringer ply drop-off locations, and are approximately $5350 \mu\epsilon$, as seen in Figure 5.10. Examination of Figure 5.11 yields maximum strain values in the same location as those found in the linear analysis, except that the value is now approximately $5650 \mu\epsilon$. Therefore, the nonlinear strain value is about 6% higher than the linear strain value. Again, this is a demonstration that the semi-span response is mildly nonlinear.

Lastly, comparison of linear and nonlinear buckling results for several models indicates that there is very little difference between the linear and nonlinear calculated buckling load factors. Therefore, it is concluded that the composite semi-span as modeled is globally linear, but that it has mild geometrically nonlinear response in localized regions. Since several of the localized regions that exhibit geometrically nonlinear response are located in the areas of interest, e.g., stringer runouts, nonlinear analyses were performed in order to obtain the required static response results. Nonlinear results for the undamaged semi-span are investigated for strain and failure up to a load factor of 1.0 DUL, and up to a load factor of 0.475 DUL for the damaged semi-span scenarios. The load factor of 0.475 represents approximately 0.7 of design limit load (DLL), which is the maximum loading that must be sustained by the damaged semi-span. However, linear buckling analyses were conducted to determine the buckling response of the composite semi-span.

5.2 Tables

6. Root Mount Plate Analysis

Utilizing the loads model, linear STAGS runs were conducted for the three load cases to investigate the forces and stresses associated with the root mount plates of the composite semi-span test article. Results of interest include the reaction forces at the wall, the root plate stress resultants along the wall, and the stresses in the plates. The reaction forces and stress resultants are provided for use in determining the bolt arrangement and sizing performed by NASA Langley. Stresses in the root mount plates are studied in order to determine whether failure will occur under the three specified load conditions.

6.1 Failure Requirements

The root mount upper and lower plates are fabricated from 6 inch thick 7075-T651 aluminum stock. Military handbook MIL-HDBK-5G, dated 1 November 1994, provides a set of allowable stresses for plates up to 4 inches thick. Therefore, linear extrapolation was used to estimate the allowable stresses for the 6 inch thick plate stock. From the graph and linear extrapolation shown in Figure 6.1, the following allowables are obtained: tension ultimate = 52 ksi, tension yield = 40.5 ksi, compression yield = 33.5 ksi and shear ultimate = 32 ksi. Data points were plotted at the lower limit of the stock thickness ranges, e.g., for 3.5 to 4.0 inch thick stock the value was plotted at 3.5 inches. Boeing assumes no extrapolation and assumes the strength properties of the 6.0 inch thick plate are the same as the 3.5 inch thick plate.

The fore and aft shear mount plates are fabricated from much thinner 7075-T651 aluminum stock, and allowables can be found directly from the table given in MIL-HDBK-5G. For the 0.5 inch plate stock, the handbook provides the following values: tension ultimate = 77 ksi, tension yield = 70 ksi, compression yield = 68 ksi and shear ultimate = 44 ksi.

Failure was investigated using the effective stress, or von Mises stress, σ_{eff} . This stress was compared to the ultimate stresses as per the maximum distortion energy criteria. Note that ultimate stresses are used instead of the yield stresses. This is because the limit load forces have been multiplied by a factor of safety equal to 1.5 to get the ultimate load forces that are used in the finite element analysis, and which have been given in Table 2.1.

6.2 Results

6.2.1 Reaction Forces

Reaction forces obtained at the wall are of translational type only due to the boundary conditions described in Section 3.3.1. Figures 6.2-6.25 show force plots for the top plates and bottom plates along the y-direction, and for the fore and aft shear plates along the z-direction. Both forces and node location are in the global coordinate system, where the wall is parallel to the yz-plane. There are no reaction moments at the interface between the root mount plates and the wall.

For all load cases and plates, the force F_x plots represent reasonable results as seen in the figures. However, both the F_y and F_z forces behave poorly near the plate separations and the shear plate connection corners. This can especially be seen in the F_z force for the top and bottom plates for all three load cases. A mesh refinement in these separation regions should better determine the forces along the

wall at these points. However, away from these corners the forces shown in the figures are reasonable and no further analysis was carried out since the results obtained were deemed sufficient.

6.2.2 Root Plate Stress Resultants

Forces along the wall have been plotted as stress resultants in order to get the running load for the plate edges located along the wall. Stress resultants for the semi-span root mount plates were generated, and the results for the first three rows of finite elements plotted. The three stress resultants, N_x , N_y and N_{xy} are plotted for each of the three load cases for the upper, lower, fore and aft root mount plates as shown in Figures 6.26-6.37. Large gradients tend to occur at the free corners of the upper and lower plates, again suggesting that refinement of the mesh may be necessary in these areas to accurately capture the response.

6.2.3 Root Plate Stresses

Stress results are presented in the form of plots showing the stress contours for the upper and lower fibers of the plates. Upper and lower fiber designations refer to the extreme fibers of the plates relative to the reference surface, and are indicated by the reference surface material axes. The material axes are located such that the positive z-axis is parallel to the surface normal as determined by the geometry. All surfaces used to generate the root mount plate finite elements have normals which point outward from the root mount plates. That is, the lower fibers are on the inside of the root mount plates toward the test article, and the upper fibers are on the outside of the root mount plates away from the test article.

The von Mises stress is given in Figures 6.38-6.40 for the top root mount plates and in Figures 6.41-6.43 for the bottom root mount plates. Since the stresses in the fore and aft root mount shear plates are lower than the top and bottom plates, and since the ultimate stress value for these shear plates is higher, results for these shear plates are omitted for brevity. It can be seen from the figures that load case 2, the 2.5G up-bending load condition, generates the highest stresses in all of the mount plates, and load case 3, the braked roll condition, generates the lowest stresses in the root mount plates. Thus, the 2.5G load condition results for the top and bottom mount plates are studied in order to predict if failure will occur.

The highest value of stress in the root mount plates occurs in the bottom plates on the lower surface, where $\sigma_{eff}=69.87$ ksi. This calculated value is 34.2% higher than the allowable ultimate tensile stress, and thus a possibility of failure for the root mount plates exists. Additionally, it can be seen that this high stress level occurs at the location where the plate bends in both the vertical and horizontal directions. That is, the highest stresses occur near the wing root rib where the plate has a change in sweep angle, particularly on plate 3. It can also be seen that upper plate number 3 and lower plate number 2 obtain stress levels that also suggest a possibility of failure. Therefore, under the 2.5G up-bending loading condition, three root mount plates demonstrate stress levels that indicate possible failure.

It appears from the linear finite element analysis for the root mount plates and the composite semi-span that several of the root mount plates indicate a possibility of failure under load case 2. The highest stress occurs in the obtuse angles on the aft edges of the plates, and dissipates forward and spanwise from this point. This location of the highest stress is expected since the corner has a stress concentration due to the change in sweep.

7. Semi-Span Buckling Analysis

7.1 Buckling Requirements

The buckling design requirement for the composite semi-span is that the fundamental buckling load factor must be greater than 1.1 DUL. In order to ensure that the requirement was satisfied, linear buckling analyses were carried out on several of the models. Results for these analyses are presented in the following sections.

7.2 Results

7.2.1 Refined Model

7.2.1.1 Undamaged

Linear buckling analysis with the refined model showed that many buckling load factors associated with overhang buckling did not satisfy the buckling design requirement, particularly for the 2.5G up-bending. However, the most important instance of low buckling load factors was associated with upper cover skin bay buckling for the 2.5G up-bending load case. Figure 7.1 shows the mesh refinement necessary in the area of the upper skin bay buckling location to accurately capture the mode shapes and load factors. Mode shapes for the two violating load factors, 1.0025 and 1.0835, are shown in Figures 7.2 and 7.3, respectively. Only the upper cover is plotted in these two figures. It is seen that these modes primarily encompass the upper cover skin bay that is bounded by the forward spar, stringer #2, rib 4 and rib 5. The skin thickness for this particular bay was provided as 5 stacks.

Because this model did not satisfy the buckling design requirement, no further analyses were carried out on this model. Instead, a recommendation was made by AS&M, and subsequently adopted, in which an extra stack was added to this upper cover skin bay. To demonstrate the effectiveness of this skin thickness correction, the detailed model was developed and analyzed.

7.2.2 Detailed Model

7.2.2.1 Undamaged

Linear buckling analyses were carried out on the detailed model in order to determine the critical buckling load factors for the three load cases and demonstrate the effectiveness of the upper cover skin thickness correction proposed by AS&M. Results for the undamaged detailed model are presented in Tables 7.1-7.3. It is seen from the tables that the semi-span passes the 1.1 DUL buckling requirement for the 1.0G down-bending and braked roll load cases. However, for load case 2, 2.5G up-bending, two buckling modes occur for load factors less than the required 1.1 DUL. These modes are along the overhang at the trailing edge of the upper cover and are 1.0834 and 1.0901. As discussed in Section 7.2.2.3, a small reduction of the overhangs increases the buckling load factors above the required value.

Figures 7.4 and 7.5 show the mode shapes that are associated with the first two skin bay buckling load factors for the detailed model, which are 1.3433 and 1.4333, respectively. Therefore, it is seen that the recommendation by AS&M of increasing the skin thickness by 1 stack at the stringer #1 runout between ribs 4 and 5, from 5 stacks to 6 stacks, corrects the skin bay buckling problem.

7.2.2.2 With Discrete Damage

The buckling analysis discussed in the following two subsections for the damaged wing is discussed in accordance with the undamaged buckling requirement. However, the wing with discrete damage is required be able to sustain only 70% of DLL. Therefore, buckling load factors above DUL do not represent a problem for the damaged wing, and the results presented in these subsections should be viewed accordingly.

7.2.2.2.1 Upper Cover Sawcut

The linear buckling load factors for the detailed model having the upper cover sawcut discrete damage described in Section 4.1 are shown in Tables 7.4-7.6. As with the undamaged detailed model, it is seen that the semi-span passes the 1.1 DUL buckling requirement for the 1.0G down-bending and braked roll load cases. However, there are now three buckling load factors below the design requirement for the 2.5G up-bending load case. Again, these modes are present in the overhangs and can be corrected by decreasing the length of the overhangs.

7.2.2.2.2 Lower Cover Sawcut

The linear buckling load factors for the detailed model having the lower cover sawcut discrete damage described in Section 4.2 are shown in Tables 7.7-7.9. As with the undamaged and upper sawcut damaged detailed models, the composite semi-span with the lower cover sawcut satisfied the buckling design requirement for the 1.0G down-bending and braked roll load cases. Although, there is only one buckling load factor for the 2.5G up-bending which does not satisfy the 1.1 DUL requirement. It is also seen that a second buckling load factor is nearly equal to the buckling requirement. Again, note that these buckling modes occur in the overhangs.

7.2.2.3 Elimination of Overhang Buckling

Although the composite semi-span wing box on a real aircraft would not have unsupported overhangs, the test article that is being investigated does have unsupported overhangs. Since it is desirable to have the buckling load factors of the overhangs also satisfy the buckling design requirement, an adjustment to the overhang length was required. It may seem logical to simply cut off a significant portion of the overhang to correct this buckling problem. However, investigation of the strains yielded the fact that the overhang is carrying significant load. Therefore, cutting off the overhang introduces more load in the upper cover skins, resulting in many areas of failure that do not occur with the full 4.25 inch overhang.

An investigation into the effect of overhang length on the fundamental buckling load factor was carried out in order to determine the minimum overhang reduction that would satisfy the buckling requirement. Using the 2.5G up-bending load case, analyses for overhangs of 3.65 and 4.25 inches were carried out and compared. The 3.5 inch overhang has a fundamental buckling load factor of 1.4170, and the 4.25 inch overhang has a fundamental buckling load factor of 1.0834. Performing a linear interpolation between the 3.65 inch and 4.25 inch overhang lengths provides a fundamental buckling load factor of 1.1 at an overhang length of approximately 4.2 inches. Thus, a conservative and practical overhang length was determined to be 4.0 inches. The buckling load factors for the modified detailed model with 4.0 inch overhangs under the 2.5G up-bending load case are given in Table 7.10. Examination of Tables 7.2 and 7.10 indicate that modifying the overhang length from 4.25 to 4.0 inches changes the locations of the buckling modes and their load factor values. The fundamental buckling mode for the 4.25 inch overhang is located in the aft overhang, and the fundamental buckling mode for the 4.0 inch overhang is located in the fore overhang. The fundamental buckling load factor associated

with the fore overhang buckling mode for the 4.0 inch overhang is seen to be 1.2088. Thus, overhang length reduction to 4.0 inches satisfies the buckling design requirement for all three load cases. Therefore, as mentioned in Section 3.3.3, the 4.0 inch overhang was adopted for use as the basis for subsequent models.

7.2.3 Tapered-Height Model

Examination of the buckling results for the detailed model indicate that there are no buckling load factors below or near the allowable value of 1.1 DUL for load cases 1 and 3. Additionally, only load case 2 exhibits buckling modes for the damaged model in the vicinity of the model changes, namely the tapered upper cover stringer runouts added in order to create the tapered-height model. Therefore, only results for load case 2, the 2.5G up-bending load case, are of interest and are presented for the undamaged and discrete damaged tapered height model.

7.2.3.1 Undamaged

Linear buckling analysis of the undamaged tapered-height model was performed and the results are presented in Table 7.11 for the 2.5G up-bending load case. As seen in previous such analyses, overhang buckling dominates. It is also seen that the fundamental buckling load factor has dropped from 1.2088 in the detailed model to 1.1518 in this tapered-height model. This load factor still satisfies the buckling design requirement, and no other adverse buckling effects are observed as a result of introducing the tapered stringer blade height for the stringer #2 and stringer #10 runouts.

7.2.3.2 With Discrete Damage

As with sections 7.2.2.2.1 and 7.2.2.2.2, the results in the following two subsections should be viewed with the understanding that the damaged wing is required to carry only 70% of DLL.

7.2.3.2.1 Upper Cover Sawcut

Linear buckling analysis of the discrete damaged tapered-height model with the upper cover sawcut described in Section 4.1 was performed and the results are presented in Table 7.12 for the 2.5G up-bending load case. It is seen that the fundamental buckling load factor has dropped slightly from 1.1518 in the undamaged tapered-height model to 1.1466 in this tapered-height model with the upper cover sawcut. Although this fundamental buckling load factor still satisfies the buckling design requirement, an additional response was observed as a result of introducing the upper cover sawcut to the tapered-height model. Specifically, the second buckling mode, which now occurs on the aft portion of the upper cover, now includes the skin bay with the stringer #10 runout and the next outboard skin bay. Figure 7.6 shows this buckling mode. Presence of the skin bays in this buckling mode indicates that nonlinear effects may be important in this region as a result of the upper cover sawcut being added.

The 1.0G down-bending and braked roll load cases were not investigated for this damage scenario since this discrete damage is expected to have little effect on the semi-span buckling response for these two load cases.

7.2.3.2.2 Lower Cover Sawcut

Linear buckling analysis of the discrete damaged tapered-height model with the lower cover sawcut described in Section 4.1 was performed and the results are presented in Table 7.13 for the 2.5G up-bending load case. It is seen that the fundamental buckling load factor has dropped slightly from 1.1518

in the undamaged tapered-height model to 1.1414 in this tapered-height model with the lower cover sawcut. This fundamental buckling load factor still satisfies the buckling design requirement and no additional adverse response was observed as a result of introducing the lower cover sawcut to the tapered-height model.

The 1.0G down-bending and braked roll load cases were not investigated for this damage scenario since this discrete damage is expected to have little effect on the semi-span buckling response for these two load cases.

8. Semi-Span Strain Prediction/Failure Analysis

Strain prediction and failure analysis of the composite semi-span was carried out using both linear and nonlinear analysis. Models with and without discrete damage, as described in Sections 3 and 4, were investigated. Contour plots of strain values are used to present the response of the semi-span for the three load conditions. Failed elements and their associated factors of safety are provided in tables, and plots are given to show the locations of the failed elements within the semi-span. Allowable values of strain for undamaged and damaged material were provided to AS&M through NASA Langley.

8.1 Failure Requirements

Within the context of this report, failure of the semi-span is defined as the calculated strain value exceeding the provided allowable strain value, despite the fact that such a situation does not necessarily indicate that structural failure will occur. As such, the term failure as used in this report simply indicates that the allowable strain value is exceeded at the specified location. These allowable strain values are given for material that will not be damaged and for material that might be damaged, and will be referred to as the undamaged and damaged allowables, respectively. Calculated strain values are compared directly to the allowable strain values since the DUL conditions are applied in the finite element models used in this study. The calculated strain values are given in the component's material coordinate system for comparison to the allowables. Undamaged strain allowables are given in Table 8.1 and damaged strain allowables are given in Table 8.2 for the upper skin, lower skin and spars. Rib strain allowables are different in that they are provided in terms of principal strains. The undamaged and damaged values for the rib material are given in Table 8.3. Table 8.4 gives the tension and compression moduli for the composite semi-span, and Table 8.5 gives the ultimate stress failure values which were used to calculate the strain allowables shown in Table 8.1. Allowable strain values shown in Tables 8.2 and 8.3 were provided directly.

A FORTRAN program was written that takes the PATRAN neutral file for the models and creates a session file with PCL commands. This session file is then run in PATRAN, creating groups for each property set which contains elements. Therefore, each group can be displayed, and the strains for each group plotted. However, in PATRAN, the default using the BASIC results option is to extrapolate strain values to the nodes and then average the nodal values. These averaged nodal values are used to make the fringe plots. Unfortunately, this method has a tendency to "wash out" the large values of strain for some elements if they are surrounded by elements with low strain, especially if the averaging domain is chosen improperly. Individual element strain values can be plotted with PATRAN, but this requires the ADVANCED option in the results menu which has a tendency to cause PATRAN to crash when using STAGS results. Although the crashing problem was corrected in later versions, the attempt to use PATRAN for determining the maximum and minimum values of strains in each property set was abandoned.

In order to accurately study the failure of the elements, a new FORTRAN program was written which compares the element centroidal strain to the allowable for the property set to which the element belongs. This program wrote the values to files representing the top surface, bottom surface and mid-plane strains. When an element is determined to fail, the element number and strain results are written to the appropriate file for the top, bottom and mid-plane surface failures. The maximum and minimum values of strain for each property set are also determined and recorded. Only mid-plane failure of the elements is investigated in this study since the provided allowable strain values are associated with the mid-plane. However, STAGS strain results are obtained at the centroid for the reference, top and bottom surfaces of the shell elements. Since many elements have offsets, the reference surface is not necessarily the mid-

plane of an element. As a result, although the reference surface is continuous, element mid-plane surfaces are not continuous which can lead to significant jumps in mid-plane strain across thickness boundaries. Therefore, the FORTRAN code processes the STAGS data and calculates mid-plane strain values for use in the failure analysis without regard to mid-plane strain continuity across thickness change boundaries. This code then uses the strain allowables, which are provided to the code via association with the element property set identification numbers, to determine failure. Lists of failed elements for each property set are saved to files for easy identification.

Since the failure analysis is carried out for mid-plane strain values only, when significant bending occurs, the failure analysis can be in error. Therefore, an additional feature was added to the FORTRAN code to calculate the significance of bending in the elements. This was accomplished by taking the top-surface strain and subtracting the mid-plane strain, dividing by the top-surface strain, and representing the result as a percent value. Mathematically this is represented by:

$$\text{percent bending} = \frac{\epsilon_{xx_{top}} - \epsilon_{xx_{mid}}}{\epsilon_{xx_{top}}} \times 100\%$$

Positive and negative values indicate the direction of the bending. However, it is the magnitude of the percent bending value that is of importance since larger absolute values represent higher bending effects. Therefore, elements for which the percent bending absolute value is greater than 20% had the mid-plane and top-surface strains provided to NASA for use in a failure analysis where bending effects are considered.

8.2 Results

Nonlinear analyses were completed for several models for each of the three load cases, and strain values calculated. As mentioned earlier, the strain values are calculated in the material coordinate system of the part under consideration. For the models studied, only the 2.5G up-bending load case produced significant strain values. Significant refers to those strain values that are close to the design allowables. Strain values for the 1.0G down-bending and braked roll load cases are much lower than the design allowables. Therefore, the results for these load cases are not discussed and are omitted for brevity. Additionally, the only components of interest are the upper and lower covers and the stringers. The material coordinate systems for these three components are set up so that the x-axis is oriented along the length of the stringer.

Two models are examined in this results section, namely the detailed model and the tapered-height model. The detailed model is presented as the baseline model for the composite semi-span strain and failure discussion. The tapered-height model is then presented to show the effects of tapering the upper cover stringer height on the strain and failure predictions.

8.2.1 Detailed Model

8.2.1.1 Undamaged, Strain

Strain plots for the composite semi-span were made using PATRAN. Strains were plotted for the top and bottom surfaces of the elements since these are the results returned from the STAGS analysis. Mid-plane strain plots were not made since the mid-plane strain values were calculated from the STAGS output in a custom program, and could not be plotted directly in PATRAN with the output provided from

STAGS. As discussed in the subsequent failure section, strain levels within the main body of the semi-span satisfied the strain requirements for the three loading conditions. Therefore, overall strain plots are of little interest except for providing some insight into the areas of highest strain. However, load case 2 strain results for the upper and lower covers are shown in Figures 8.1 and 8.2 as being representative of the obtained results since these provided the highest strain values. Lastly, Figure 8.3 shows a close-up of the top surface strains for the upper cover in the vicinity of the stringer #10 runout. It is seen from this plot that the overhang exhibits the nonlinear behavior discussed in Section 5.1, leading to the overhang element failures discussed in the following section.

8.2.1.2 Undamaged, Failure

Failure analysis of the undamaged composite semi-span using undamaged allowables indicates that there are no regions within the main body of the semi-span that exhibit strain failures. The main body is defined as all elements interior to the spars, which includes everything except the overhangs. However, using the definition of failure provided earlier, numerous upper cover overhang elements were seen to exhibit failure for load case 2. Details of the failed overhang elements are not reported since the overhang response was, in general, not the focus of the current investigation, but a brief discussion follows.

Failure of the overhang elements can be attributed to the nonlinear behavior of the overhang, which causes significant bending in local regions of the upper cover overhang. Figure 8.4 shows the elements in the vicinity of the stringer #10 runout that exhibited greater than 20% bending as defined in Section 8.1. Several elements in the overhang are seen to exhibit this excessive bending, as are many elements at the stringer termination. As stated earlier, elements exhibiting excessive bending require additional failure analysis since the mid-plane strain evaluation is insufficient. Also seen in the figure are trapezoidal elements that are scattered across the region, but these elements do not accurately represent the large bending effects. Tests were performed where the trapezoidal elements were removed and a regular (nearly rectangular) mesh was generated. Results from the regular mesh did not exhibit the large bending effects in the areas where the trapezoidal elements were removed. Therefore, it was concluded that the strain results of the trapezoidal elements in STAGS are questionable, so trapezoidal elements were avoided near regions of interest and were only used for mesh transition in regions where their results can effectively be ignored.

8.2.1.3 With Discrete Damage, Strain

Analysis of the detailed model with discrete damage was performed using the undamaged allowables for load factors up to 0.475 of DUL. This value is slightly above 70% of DLL, which is the design load factor for these damage scenarios. Load case 1 and 3 strain values are significantly below the allowables for both damage scenarios and no further discussion is included. Results for load case 2 are discussed in the following two sections.

8.2.1.3.1 Upper Cover Sawcut

Strains throughout the main body of the composite semi-span are within the allowable values. The only exception to this is at the crack tips. Figure 8.5 shows the spanwise top surface strains in the vicinity of the sawcut, with Figure 8.6 showing a close-up of the forward most crack tip region strains. As expected, the crack tip acts as a stress concentration where the strains exceed the allowable strains for a distance of approximately 0.3 inches from the crack tip.

8.2.1.3.2 Lower Cover Sawcut

Similar to the upper sawcut model, the lower sawcut model exhibits strains throughout the main body of the composite semi-span within the allowable values. Figure 8.7 shows the spanwise top surface strains in the vicinity of the sawcut, with Figure 8.8 showing a close-up of the forward most crack tip region strains. As expected, the crack tip acts as a stress concentration where the strains exceed the allowable strains for a distance of approximately 0.2 inches from the crack tip.

8.2.1.4 With Discrete Damage, Failure

As with the strain results, only load case 2 results are discussed in the following two sections on failure of the composite semi-span with discrete damage, and failure is based upon the undamaged allowables. This failure discussion only focuses on the prediction of failure for elements based on the original model configuration, with failed elements continuing to contribute to the strength of the structure. That is, no progressive failure analysis or crack propagation analysis was carried out on the composite semi-span. Results from those two types of analysis could yield response significantly different from the analysis carried out and reported herein. Therefore, the presented results should be viewed accordingly.

8.2.1.4.1 Upper Cover Sawcut

Only elements in the vicinity of the crack tip exhibited failure under 2.5G up-bending for load factors up to 0.475 of DUL. Failure initiated in the triangular elements located at the crack tip at a load factor of 0.2. Successive element failures were observed as the load factor gradually increased to the 0.475 maximum. Figures 8.9-8.12 show the failed elements for each load factor at which any elements first exhibit failure. The skin thickness at both crack tips is the same, and since the strains given in Figure 8.5 are fairly symmetric, so are the failed regions shown in the figures. Lastly, factors of safety and margins of safety associated with the failed elements are provided in Table 8.6 for a load factor of 0.475. Also provided in the table are the strain allowable and the calculated strain value for each element.

8.2.1.4.2 Lower Cover Sawcut

The lower cover sawcut model response was similar to the upper cover sawcut model response. Failure initiated at the crack tip at a load factor of 0.2 and successive element failures occurred as the load factor increased to 0.475. Figures 8.13-8.15 show the failed elements in the lower sawcut model for each load factor at which any elements first exhibit failure. Contrary to the upper sawcut model, the lower sawcut model has different skin thicknesses at the two crack tips. However, the allowable is the same everywhere for the lower skin, so since the strains in Figure 8.7 are nearly symmetric about the crack tips, the failure pattern is also nearly symmetric as seen in the figures. Table 8.7 gives the factor of safety, margin of safety, strain allowable and calculated strain for each failed element at a load factor of 0.475.

8.2.2 Tapered-Height Model

8.2.2.1 Undamaged, Strain

Analysis of the composite semi-span was carried out using the tapered-height model described in Section 3.3.4, and strains are similar to those of the detailed model with the exception of the stringer runout areas. A close-up of the upper cover strains in the vicinity of the stringer #10 runout was shown in Figure 5.11 in conjunction with the nonlinearity discussion. No further strain results are presented.

8.2.2.2 Undamaged, Failure

The 2.5G up-bending load case was used in the tapered-height failure analysis since it has been shown to be the critical load case. As discussed in Section 8.2.1.2, failure analysis at 1.0 DUL for the detailed model indicates that no main body elements fail. On the other hand, the tapered-height model indicates that three main body regions exhibit element failure when the damaged allowables are used.

Since the tapered-height model was derived from the strain gage model, numerous regions in the tapered-height model are highly refined when compared to the detailed model. One of these regions is the aft portion of the lower cover cutout located between ribs 7 and 8. As a result, the tapered-height model indicates that the stress concentration that occurs at the cutout edge initiates element strain failure at a load factor of 0.9. Figures 8.16-8.18 show the failed elements around the cutout for load factors of 0.9, 0.95 and 1.0, respectively. Factors of safety and margins of safety for the failed elements at DUL, based on the damaged allowables, are given in Table 8.8, with element numbers shown in Figure 8.19.

Additional failures initiate in the stringer #2 and #10 blades at 0.8 DUL load factor. Figure 8.20 shows the ply drop-off locations in the region of the stringer #10 runout. Failed elements for stringer #10 are then presented in Figures 8.21-8.24 for load factors of 0.8, 0.9, 0.95 and 1.0 DUL, respectively. A study of these failed elements indicates that the failures initially occur at the ply drop-offs, where the thicker region dumps the load into the reduced thickness region. All failed elements occur in the 2-, 4- and 6-ply regions, which have damaged allowables of 4132, 4132 and 4158 microstrain, respectively. Similarly, element failures occur in stringer #2 in the 4- and 6-ply thickness areas. Ply drop-offs for stringer #2 are shown in Figure 8.25, and stringer #2 failed elements are shown for load factors of 0.8, 0.9, 0.95 and 1.0, respectively, in Figures 8.26-8.29. Factors of safety and margins of safety are not provided for the stringer #2 and #10 blades for the results based on the damaged allowables.

Therefore, it is concluded that the height taper for stringers #2 and #10 at the runouts causes significant failures when damaged allowables are utilized. However, since the test article is not to be impacted on the stringer blades, failure analysis based on undamaged allowables can be considered for the stringer #2 and #10 blades. Comparison using undamaged allowables indicates that no stringer blade elements fail. Thus, as long as no damage is introduced to the stringer blades, the tapered height runouts of stringers #2 and #10 should perform safely during the composite semi-span testing. However, element failures found while using the damaged allowable for elements located along the aft edge of the lower cover cutout between ribs 7 and 8 indicate that this area can not have impact damage introduced. However, as with the stringer blades, the lower cover elements in this cutout region do not exhibit failure when utilizing the undamaged allowables. Finally, refinement around the edges of the remaining lower cover cutouts may reveal similar behavior, but such an investigation was not conducted for presentation within this report.

8.2.2.3 With Discrete Damage, Strain

Strain results for the tapered height model with discrete damage are similar to those of the detailed model with discrete damage discussed in Section 8.2.1.3 and its subsections. Therefore, no further results are presented in this section.

8.2.2.4 With Discrete Damage, Failure

Failure results for the tapered height model with discrete damage are similar to those of the detailed model with discrete damage discussed in Section 8.2.1.4 and its subsections. Therefore, no further results are presented in this section.

9. Semi-Span Strain Gage Prediction

The Government provided locations for the strain gages that will be included in the testing of the composite semi-span. At the request of the technical monitor, only those strain gages located on the upper and lower covers and their attached stringers, and indicated in Tables 9.1 and 9.2 were studied by AS&M. Strain gage predictions were made either by extracting element centroidal strain values from the STAGS output or by being calculated from the nodal displacements. For both of these methods, extrapolation of values was generally required. Due to the extremely large number of data points, the strain gage predictions were generated by a FORTRAN code that was written in order to automate and expedite the procedure. To ensure convergence of the strain gage predicted results, a convergence study was carried out using the undamaged detailed model as the starting point.

9.1 Convergence Study

The convergence study was initiated using the undamaged detailed model as the basis. Convergence was studied at a load factor of 1.1 DUL using the 2.5G up-bending load case results. Due to the lack of lower cover fidelity in the detailed model, gages 114 and 118 were omitted from the basis calculations. Areas with strain gages present were then refined and the strain gage values recalculated. When reasonable strain gage value convergence was observed for a particular convergence study step, further refinement was not carried out in the vicinity of that strain gage in subsequent steps. Reasonable convergence was defined as strain gage predicted value changes on the order of 2% or less between successively refined models. This process was carried out several times until the desired level of convergence was obtained. It is interesting to note that on several occasions, meshes which were "more refined" than the previous mesh demonstrated adverse convergence qualities. This behavior was linked to the presence of triangular elements, which were required for mesh transition, being too close to the strain gage location. Therefore, it is demonstrated that the introduction of triangular elements in a primarily quadrilateral mesh near the region of interest for strain predictions is contraindicated. Figure 9.1 shows the original mesh and Figure 9.2 shows the final mesh in the region of strain gages 10 and 11.

9.2 Results

9.2.2 Strain Gage Model

Results for all three load cases were obtained for the undamaged strain gage model. For the strain gage model with the upper cover sawcut discrete damage, only load case 2 was studied. No strain gage predictions were made for the semi-span with the lower cover sawcut discrete damage.

9.2.2.1 Undamaged

After selection of a mesh which provided satisfactory convergence behavior, strain gage predictions for the three load cases were made for the undamaged wing. Tables 9.4-9.6 provide the strain gage predicted values, in microstrain, at their associated load step values for the three load cases. Load step values for load cases 1 and 2 are given for actuator #2, while for load case 3 the load step values are given for actuator #7a. The load step value is equal to the load factor times the actuator DUL value at that particular nonlinear load step.

Plots of strain gage value as a function of load step value show that most strain gages demonstrated linear behavior for all three load cases. Although several gages exhibited nonlinear behavior for load case 3, these gages were located in regions of very low strain, and therefore of little interest. Plots of strain versus load for strain gages that exhibited interesting behavior are shown in Figures 9.3-9.17, and the associated strain gage numbers are tabulated in Table 9.7 for reference.

9.2.2.2 With Discrete Damage

9.2.2.2.1 Upper Cover Sawcut

The strain gage model with an upper cover sawcut was studied and the effect of the upper cover sawcut presence on the strain gage values determined. However, the strain gage locations studied were limited to those whose results are given in Table 9.8, i.e., only those strain gages whose response would expect to be affected by the introduction of the crack. Also, only load case 2 was investigated for this damaged model. Additionally, although the test for this damaged case will not progress to as high a load level as that for the undamaged semi-span, results are again presented up to 1.1DUL (recall that the test is only expected to progress to about 0.47 DUL). As seen by the response of strain gage 332, which is shown in Figure 9.18, even at these high load levels the response of the strain gages near the crack remains linear (gage 332 is 0.5 inches from the crack tip). Strain gages exhibiting nonlinear behavior for this case are the same as for the undamaged wing given in Table 9.7 with the exclusion of gages 254, 255, 319, and 323. Plots for the nonlinear strain gage response of the upper cover discrete damaged strain gage model under load case 2 loading are given in Figures 9.19-9.24.

Finally, some remarks about the discretization near the crack tip and its effect on the response of the strain gage predicted values is warranted. The mesh at the upper cover aft crack tip shown in Figure 9.25 was used in the strain gage predictions. Far field outer surface strains, ϵ_{xx} , which are found with this discretization are shown in Figure 9.26, with a close-up of the crack tip shown in Figure 9.27. A refinement of the mesh near the crack tip was carried out, providing the discretization shown in Figure 9.28. Far field outer surface strains, ϵ_{xx} , which are found with this highly refined discretization are shown in Figure 9.29, with a close-up of the crack tip shown in Figure 9.30. The contour scale for these two figures is the same as that in Figures 9.26 and 9.27, respectively, which has the maximum compressive strain predicted by the mesh in Figure 9.25 as the lower limit. Note, however, that the strains in the region of the strain gage, at a distance of approximately 2.5 times the crack width from the crack tip, are approximately the same. In fact, the predicted values for gages 331 and 332 are within an acceptable value of 2% for the two meshes. However, as seen in Figure 9.41, which uses the maximum compressive strain predicted by the discretization of Figure 9.28 as the lower contour limit, the crack tip strain has increased approximately two and a half times from the coarse mesh to the refined mesh (from 2989 $\mu\epsilon$ to 7512 $\mu\epsilon$). Since it is the strain gage predicted value that is of importance, and not an accurate prediction of the crack tip strain, the coarse mesh provides sufficient results. Therefore, using one element edge length to span the region of high strain gradient, then introducing only a few more elements up to the strain gage location is a reasonable meshing practice for determining strain gage predictions. That is, the "pointed" crack tip of Figure 9.25 does not adversely affect the predicted strain gage results when compared to the "round" crack tip, provided that the strain gage is sufficiently "far" from the crack tip and a reasonable mesh is used. Lastly, the refined mesh in Figure 9.28 increases model size by approximately 7-8% over the model with the mesh shown in Figure 9.25, which is an unnecessary and undesired result.

10. Semi-Span Deflection Prediction

Deflection results for the three load cases were required at various location on the composite semi-span test article. Displacements at the actuator ends attached to the semi-span and at the intersection points of rib 2 and the lower cover with the fore and aft spars were found (10 locations per load case). A convergence study was carried out and the results reported only for the undamaged detailed model.

10.1 Convergence Study

A convergence study was carried out using the detailed model and the strain gage convergence study models. Comparison of the detailed model displacement results with the first strain gage convergence study model refinement indicated that, as expected, the refinement for the strain gages has no effect on the predicted displacements at the desired ten locations. Tables 10.1-10.8 show the error comparison between these two models for the global displacement components under the 2.5G up-bending load condition at the eight actuator locations. It is seen that with the exception of the x-displacement errors for actuator 7b shown in Table 10.7, none of these values exceeds 1%. The larger errors found for the actuator #7b x-displacement, especially at smaller load factors, is easily explained by noticing that the actual x-displacement value is extremely small (see Table 10.25). However, for higher load factors the errors in the x-displacement quantity are still within a few percent between the two models, so the displacement results found using the original finite element mesh for the detailed model are taken as being converged and are presented herein.

10.2 Results

Displacement result values for the load factors given in Table 2.2 are presented in terms of actuator loads. For the 1.0G down-bending and the 2.5G up-bending load cases, load values are provided for actuator #2, and for the braked roll load case, load values are provided for actuator #7a. Lastly, since introduction of small, localized damage is not expected to affect the overall displacement response of the composite semi-span, results are only presented for the undamaged detailed model.

10.2.1 Detailed Model

10.2.2.1 Undamaged

Displacement results at the desired ten locations are provided in Tables 10.9-10.18 for 1.0G down-bending, Tables 10.19-10.28 for 2.5G up-bending and Tables 10.29-10.38 for braked roll. Individual displacement component plots are shown in Figures 10.1-10.3 for the actuator #2 load node under the 2.5G up-bending loading, and Figure 10.4 shows a plot for the total displacement distance at the same node. The x-component seen in Figure 10.1 indicates mild nonlinearity at this location, whereas the y-displacement component seen in Figure 10.2 indicates that the response is highly nonlinear. However, the largest displacement component at this location is the z-displacement as seen in Figure 10.3, which exhibits nearly linear behavior. As a result, the total displacement distance shown in Figure 10.4 exhibits nearly linear response since it is dominated by the z-displacement component. Similar results are seen at the other locations for all three load cases, where any apparent nonlinear displacement component response is dominated by a nearly linear displacement component response in the total response. Thus, nodal displacement plots are provided in Figures 10.5-10.14 for 1.0G down-bending, Figures 10.15-10.24 for 2.5G up-bending and Figures 10.25-10.34 for braked roll. These compiled results are provided so that it can be determined if the actuators will exceed their maximum stroke during the testing. Lastly, overall deformation plots are provided in Figures 10.35-10.37 for the three load cases.

11. Loadarm Region Analysis with Follower Load

11.1 Follower Load Implementation

The load applied by actuator #7a for the braked roll case was made to be a follower load, with all other applied loads remaining as fixed loads in the z-direction. In previous analyses, this actuator #7a load was applied to a node attached to the loadarm plate. However, simply applying this load as a follower load does not have the required effect. This is because the conventional follower load will rotate with the node to which it is applied, whereas what is required is a load that remains oriented along the axis of the load actuator cell. Therefore, as mentioned in Section 3.3.6, a beam was added to the model to act as the load actuator cell. The applied load is therefore attached to the end node of this actuator beam, where it then becomes a conventional follower load with respect to the actuator beam.

The base of the actuator beam is fixed to the ground by setting all three translations equal to zero (see Figures 2.1, 3.15, 3.16 and 3.18 for actuator location). However, since setting only these three degrees of freedom does not restrain rigid body rotation about the beam axis, the rotation about the y-axis was also set to zero. This added boundary condition does not over constrain the system, it simply eliminates the rigid body rotation about the beam axis. The remaining rigid body rotations are eliminated when translational compatibility between the force end of the actuator beam and the loadarm plate is enforced. Translational compatibility between the actuator beam load node and the loadarm attachment node satisfies the requirement that the two nodes have the same location in space, but they are free to rotate independent of each other. It is this capability of independent rotation of the actuator beam and loadarm plate that ensures that the follower load is oriented properly. However, the connection of these two nodes turned out to be problematic.

The initial connection method for the actuator load beam and the loadarm plate was via the STAGS G2 record [1]. G2 records are used to enforce partial compatibility between displacements at particular nodes. Using this single record appeared to be the best method to use, but this turned out not to be the case. Examination of the final orientation for the follower force indicated that this method appears to orient the follower force based upon the average rotation of the connected nodes. This, naturally, is not the correct orientation for the follower force. Therefore, an alternative method which used the G3 and G4 records was implemented. These records define Lagrange constraints, permitting the user to effectively enforce the compatibility of the required degrees of freedom (translations in this case). Using this method of connection resulted in a follower force that was oriented along the axis of the actuator beam, which was the desired result. Unfortunately, this method has several difficulties that must be addressed. First, the constraint equations increase the number of degrees of freedom in the model (1 degree of freedom for each constraint). Second, constraints with large numbers of terms can have a detrimental effect on the bandwidth of the system, causing the solution time to increase dramatically. Third, numerical difficulties can arise unless the constraint is scaled so that the stiffness terms introduced by the constraint equation are of the same order of magnitude as the other stiffness matrix terms. Lastly, one negative root will appear for each constraint equation. For the semi-span test article analysis, none of these problems were of great importance since only three equations containing two terms each were introduced (one for each translational degree of freedom at the coincident nodes).

11.2 Results

Results were obtained under the follower load braked roll load case for two different cases. The first case was the semi-span with no constraint on the loadarm plate. During this analysis case, the loadarm plate is able to deform freely. The second analysis case has a constraint added so that the loadarm plate

is forced to have a small x-deflection near the actuator #7a attachment point. This constraint is necessary since the x-deflection for the actuator load node in the unconstrained case is sufficiently large as to possibly exceed the range of motion allowed by the swivel at the load actuator cell base. Discussion of the two analyses and their results follows.

11.2.1 Loadarm Model

11.2.1.1 Unconstrained Loadarm Plate

The loadarm model was first studied with no constraints applied to the loadarm plate. This is the same as for all previous analyses where the only boundary conditions are those applied to the root mount plates at the wall nodes. Therefore, the loadarm plate is able to deform freely according to the applied loading. Because of this, the loadarm plate exhibits bending and torsion that result from the actuator load being eccentrically applied with respect to the loadarm I-beam web. Figures 11.1 and 11.2 clearly show the bending and twisting response of the loadarm plate. Figure 11.1 shows the undeformed and deformed loadarm plate at DUL for a view looking down the negative z-axis, while Figure 11.2 shows the same for a view looking down the negative y-axis. The out-of-plane deformation of the loadarm plate is emphasized further in Figure 11.3 that shows a contour plot of x-deflection. Larger x-deflections seen at the actuator load end of the loadarm plate demonstrate the bending response, while the contour lines not being perpendicular to the edges indicates the twisting response. Lastly, Figure 11.4 shows the overall deflection pattern for the composite semi-span test article under braked roll with a follower load. Note that this primarily produces a torsional deformation of the semi-span as was seen with the constant direction load, but the loadarm plate suffers from additional out-of-plane deformations not seen under the constant direction load scenario.

Deflection results for three node locations have also been compiled and are presented in Tables 11.1-11.3. Figure 11.5 shows the locations of the three nodes with respect to the loadarm plate. Table 11.1 gives the deflections of node 131 of the loadarm plate, which is tied through the Lagrange constraints to the actuator beam end node. Table 11.2 gives the deflections of a node approximately 3 inches interior to the loadarm from the actuator attachment fixture, shown as node 71 in the figure. Table 11.3 gives the deflection of the uppermost leading edge node of the loadarm plate, node 6684 in the figure. Load factor/deflection plots corresponding to Tables 11.1-11.3 are shown in Figures 11.6-11.8.

Finally, the NASTRAN file of the loadarm, flat.bdf, that was provided by NASA was modified and the NASTRAN run was completed for comparison to the STAGS results. Modification of the NASTRAN input file flat.bdf was necessary since the analysis did not obtain converged nonlinear results with the input file as provided. Therefore, the plasticity effects were eliminated and the loading was reduced to DLL from DUL since testing will only be to DLL for the braked roll condition. A plot comparing deflection results of the current STAGS loadarm model with the deflection results from NASTRAN model is shown in Figure 11.9. It is seen that the x-deflections predicted by the two models are nearly identical. However, the y- and z-direction deflections are significantly larger for the NASTRAN model (approximately 20% and 14% for y- and z-deflections at DLL, respectively). This can possibly be explained by the lack of fidelity in the NASTRAN model where stringers are still primarily modeled as offset beams connected to the skins by multipoint constraints. Additionally, the regions of the stringer that are modeled as shells are not correctly attached to the portions of the stringer modeled as beams. This effectively creates discontinuous stringers, resulting in a more flexible model. Therefore, the results from the model developed by AS&M are deemed to be more accurate since the finite element model is a more accurate representation of the structure.

11.2.1.2 Constrained Loadarm Plate

The swivel joint at the base of load actuator cell #7a will allow approximately 3 inches of x-direction travel at the actuator tip. As seen by the results of Section 11.2.1.1, this limit value is exceeded at DUL. Even though loading will be stopped at DLL, enough concern is raised by the x-direction deflection of the loadarm plate that a means of reducing this x-deflection was proposed by NASA. The method consists of adding of a load actuator cell attached to the wall on one end and attached to the loadarm plate at the other end. The application location for this load actuator is approximately node 71, which is indicated in Figure 11.5. This added actuator will then constrain the attachment node to have an x-deflection equal to that of a node near the aft spar that has small x-deflection, namely node 6684 of Figure 11.5. Computationally, this is enforced by adding a fourth Lagrange constraint that ties the x-deflection of node 78 to the x-deflection of node 6684. The constraint forces can be recovered from the results, providing the forces necessary in the actuator to accomplish the loadarm deflection constraint.

Figure 11.10 shows a view along the negative z-axis of the loadarm plate mesh deflection under braked roll with a follower load and the additional x-displacement constraint. Figure 11.11 is the same as Figure 11.0 but with the view along the negative y-axis. A contour plot of the loadarm plate x-deflection is shown in Figure 11.12 under the same conditions. From this figure, it is clear that the loadarm plate still suffers from out-of-plane bending, with the central portion of the loadarm plate having the maximum x-displacement. Also, these figures clearly show that the x-deflection has been controlled successfully by the application of a load actuator cell attached between the wall and the loadarm plate.

Deflections for the three nodes shown in Figure 11.5 are given in Tables 11.4-11.6, and the associated forces at nodes 131 and 71 for the same load factors are given in Tables 11.7 and 11.8, respectively. Having both deflections and forces at these nodes provides NASA with the opportunity to program the test control program for either displacement control or load control.

12. Conclusions

Numerous analyses have been conducted in order to predict the response of a composite semi-span test article. These analyses cover undamaged and damaged scenarios for three loading conditions; 1.0G down bending, 2.5G up bending and braked roll. The models with and without discrete damage were studied for linear and nonlinear response, with stress and strain, factors of safety, buckling, deflection and strain gage responses presented in the form of tables and plots. Several performance issues have been identified and they are as follows:

1. Comparison of linear and nonlinear results for both static response and buckling response indicates that geometric nonlinearity is only important in localized regions of the semi-span test article.
2. Since scenarios for the semi-span with discrete damage are loaded to 70% of DLL, and not up to DUL as with the undamaged scenarios, only response in the immediate vicinity of the discrete damage is of interest (e.g., high strains at the sawcut tips).
3. Possible local failure problems in the root mount plates caused by the presence of the double sweep angles. The semi-span contractor assures that the failure is small and that plasticity effects will prevent structural failure.
4. Buckling of the upper cover skin panel located between stringer #2, the forward spar, and ribs 4 and 5. This problem was corrected by adding an additional skin stack to the region.
5. Buckling of the upper cover overhangs. This problem was corrected by reducing the overhang length from 4.25 inches to 4.0 inches.
6. The presence of failed elements on the aft edge of the lower cover cutout between ribs 7 and 8 in the tapered-height model for 2.5G up bending, indicating this region should not be impacted. Failed elements in the upper cover stringers #2 and 10 for the same model and loading are ignored since these regions shall not be impacted and comparison to undamaged allowables indicates no failure.
7. Excessive x-deflection of the loadarm plate when the follower load was considered for the braked roll loading condition. This problem was corrected by enforcing a maximum x-deflection by means of an additional load actuator.
8. Numerous other data was also presented in this report for comparison to the test results and for test planning.

Additional issues reported include the use of triangular elements and trapezoidal shaped quadrilateral elements in the STAGS finite element code, and the manner in which to implement the follower load. Both the triangular and trapezoidal shaped quadrilateral elements behaved poorly. This may be due to the presence of shell offsets that are present in the model. As a result, these elements were avoided in areas of interest. Lastly, several methods exist in STAGS for implementing the follower load needed to study the composite semi-span. However, even though these methods should yield identical results, it was found that only by using the G4 records to attach the coincident nodes on the loadarm plate and the actuator beam could the correct follower load action be achieved.

13. ABSTRACT (Maximum 200 words) AS&M, Inc. performed finite element analysis, with and without discrete damage, of a composite semi-span test article that represents the Boeing 220-passenger transport aircraft composite semi-span test article. A NASTRAN bulk data file and drawings of the test mount fixtures and semi-span components were utilized to generate the baseline finite element model. In this model, the stringer blades are represented by shell elements, and the stringer flanges are combined with the skin. Numerous modeling modifications and discrete source damage scenarios were applied to the test article model throughout the course of the study. This report details the analysis method and results obtained from the composite semi-span study. Analyses were carried out for three load cases: Braked Roll, 1.0G Down-Bending and 2.5G Up-Bending. These analyses included linear and nonlinear static response, as well as linear and nonlinear buckling response. Results are presented in the form of stress and strain plots, factors of safety for failed elements, buckling loads and modes, deflection prediction tables and plots, and strain gage prediction tables and plots. The collected results are presented within this report for comparison to test results.
